Abstract

The dyonic 1/4-BPS states in 4D string theory with $\mathcal{N} = 4$ spacetime supersymmetry are counted by a Siegel modular form. The pole structure of the modular form leads to a contour dependence in the counting formula obscuring its duality invariance. We exhibit the relation between this ambiguity and the (dis-)appearance of bound states of 1/2-BPS configurations. Using this insight we propose a precise moduli-dependent contour prescription for the counting formula. We then show that the degeneracies are duality-invariant and are correctly adjusted at the walls of marginal stability to account for the (dis-)appearance of the two-centered bound states. Especially, for large black holes none of these bound states exists at the attractor point and none of these ambiguous poles contributes to the counting formula. Using this fact we also propose a second, moduli-independent contour which counts the "immortal dyons" that are stable everywhere.

1 Introduction

A microscopic counting formula was proposed more than a decade ago for dyonic BPS states in the $\mathcal{N} = 4, D = 4$ theory [1] corresponding to the toroidally compactified heterotic string. The interest for this counting formula was revived about two years ago in the context of higher-order curvature corrections to the entropy [2]. Subsequently, the formula was given a proper derivation [3] using the 4D-5D connection [4] (See also [5] for a toroidal example) and the known results for the microscopic counting of five-dimensional black holes [6, 7]. A particular feature of the formula, namely the occurence of a genus two modular form, was given a novel interpretation in terms of string networks [8]. Recently, a similar counting formula was proposed for a class of more general $\mathcal{N} = 4, D = 4$ theories [9], known as the CHL models [10]. This class of models has subsequently been studied from various different angles [11].

In the meantime, various puzzles have been raised about these dyon counting formulas [12, 13]. First of all, it has been observed that there is a subtlety in checking their S-duality invariance. Secondly, there is an ambiguity in choosing the integration contour arising from the complicated pole structure of the modular forms that enter the formulas. Finally, it has been noted that the BPS spectrum in the macroscopic supergravity theory is subjected to moduli dependence due to the presence of walls of

marginal stability for some multi-centered bound states. See [14] and references therein for a discussion of this phenomenon in the $\mathcal{N} = 2$ context. Finally, either by using a duality argument [12], or by studying a specific example in great details [13], there have been some hints that all the above issues might actually have something to do with each other.

The goal of the present paper is to address these issues and provide a resolution to some of these puzzles. In particular, our aim is to present a precise contour prescription that will lead to a counting formula that is manifestly S-duality invariant. In fact, we will find two natural prescriptions of this kind, one moduli dependent and a second only depends on the charges. To arrive at these prescriptions, an important role is played by the one-to-one correspondence between various poles in the integrand of the counting formula, and the different decay channels in which a dyon can be split into two 1/2-BPS particles. This correspondence between poles and bound states was envisaged in [1], and was recently reiterated in [12, 13]. It turns out that the only poles that can be crossed when the choice of contour is varied are precisely the ones that admit such a correspondence. Moreover, we find that the contributions of the poles exactly match the expected number of states corresponding to the two-centered configurations of BPS dyons[3]. The key observation which allows us to identify the correct contour prescription is that the resulting integration contour should render the counting formula explicitly S-duality invariant, and should furthermore automatically take the (dis-)appearance of the two-centered bound states into account when a wall of marginal stability is crossed. This leads to a moduli dependent degeneracy (or index-) formula that counts all the living dyons in every region of moduli space. In particular, we observe that the walls of marginal stability have the property that for large black hole charges (as opposed to "small black holes" with vanishing leading macroscopic entropy), none of the two-centered bound states of 1/2-BPS particles can exist when the background moduli are fixed at their attractor value. Using this fact we also propose a second, moduli-independent contour prescription, which has the property of counting only the "immortal dyons" which exist everywhere in the moduli space.

The paper is organized as follows. In section two we start by reviewing the dyon

[3]Recently this fact was independently noted in [15], which appeared while this paper was being prepared.

counting formula and formulate the issue of its contour dependence. The contour dependence of the microscopic counting formula is analyzed in section three. We derive the condition for a given pole to contribute to the degeneracy formula and calculate its specific contribution. In section four we give more details of the macroscopic theory and derive the stability condition for the two-centered bound states of 1/2-BPS particles. In section five we relate the two sides and present our two contour prescriptions, one corresponding to the "jumping" index and one to the "eternity" index. Finally, we finish with some discussions and open questions in section six.

2 The Microscopic Counting Formula and the Poles

In this paper we are interested in dyonic BPS states in string compactifications to four dimensions with $\mathcal{N} = 4$ space-time supersymmetry. The simplest of these string theories is the $K3 \times T^2$ compactification of the type II string, or equivalently the toroidally compactificied heterotic string. Its U-duality group is the product of the $SL(2,\mathbb{Z})$ electric-magnetic duality and the $O(6,22;\mathbb{Z})$ T-duality group. A more general class of four-dimensional $\mathcal{N} = 4$ string theories is obtained by taking the orbifolds of the aforementioned theory. For definiteness, in the following we will present our results for the simplest case without any orbifolding, and in the end briefly comment on how, for a class (the CHL models [10]) of the orbifolded theories, the same steps can be modified and followed to arrive at a very similar result.

The BPS states that preserve one-half of the supersymmetry are well understood. Using the duality symmetries, these 1/2-BPS states can be mapped to purely electrically charged states corresponding to heterotic strings carrying only momentum and winding charges. Their degeneracy follows from the level-matching condition and the state counting of the 24 right-moving bosonic oscillators of the heterotic string. One finds

$$d(P) = \oint d\rho \, \frac{e^{-i\pi P^2 \rho}}{\eta^{24}(\rho)} \, . \tag{2.1}$$

None of these states carry any macroscopic entropy, at least not at the leading order. To obtain a macroscopic entropy it is necessary to consider BPS states which preserves

only one-quarter of the supersymmetry. Such 1/4-BPS states necessarily carry both electric as well as magnetic charges

$$(P, Q) \in \Gamma_{6,22} \oplus \Gamma_{6,22} \ , \tag{2.2}$$

and their leading macroscopic entropy is given by[4]

$$S = \pi |P \wedge Q| \equiv \pi \sqrt{Q^2 P^2 - (Q \cdot P)^2} \ , \tag{2.3}$$

where the inner product is the standard $SO(6, 22)$-invariant one on $\Gamma_{6,22}$. The counting formula for the 1/4-BPS states proposed in [1] takes the following form:

$$D(P, Q) = \oint_{\mathcal{C}} d\Omega \, \frac{e^{-i\pi \binom{P}{Q}^\dagger \Omega \binom{P}{Q}}}{\Phi(\Omega)} \, (-1)^{(P\cdot Q)+1} \ , \tag{2.4}$$

where we have incorporated the sign factor $(-1)^{P\cdot Q}$ following [19]. Here $\Phi(\Omega)$ is an automorphic form of the genus two modular group, which means that under the $Sp(2, \mathbb{Z})$ transformation[5]

$$\Omega \to (A\Omega + B)(C\Omega + D)^{-1} \tag{2.5}$$

it transforms as

$$\Phi(\Omega) \to \Big(\det(C\Omega + D)\Big)^k \Phi(\Omega) \ . \tag{2.6}$$

For the case of the toroidally compactified heterotic string the weight k is equal to 10. The automorphic form $\Phi(\Omega)$ is a well-defined function on the Siegel upper-half plane defined by

$$\det(\mathrm{Im}\Omega) > 0, \qquad \mathrm{Tr}(\mathrm{Im}\Omega) > 0 \ . \tag{2.7}$$

The precise expression for $\Phi(\Omega)$ will not be important for the purpose of our paper. The main property of Φ that will concern us is that it has double zeroes at specific loci in the Siegel domain. In the entropy formula these lead to double poles in the integrand. When one identifies Ω with the period matrix of a genus two surface, the poles in $1/\Phi$

[4]The short hand notation $|P \wedge Q|$ uses the analogy with the norm of the exterior product of two vectors. Note the r.h.s. indeed vanishes when P and Q are parallel.

[5]The 2×2 matrices A, B, C, D have all integer entries and satisfy the following relation

$$AB^T = B^T A \quad ; \quad CD^T = DC^T \quad ; \quad AD^T - BC^T = \mathbb{1}_{2\times 2} \ .$$

occur precisely at those values of Ω at which the genus two surface degenerates into two separate genus one surfaces through the pinching of a trivial homology cycle. These degenerations are labelled by elements of $Sp(2,\mathbb{Z})$ and are characterized by the fact that the transformed period matrix is diagonal. We will write this condition as

$$\Big((A\Omega+B)(C\Omega+D)^{-1}\Big)^{\sharp}=0\ , \tag{2.8}$$

where the superscript $\sharp$ denotes the upper right (or equivalently, lower left) element of the symmetric 2×2 matrix.

The poles with $C\neq 0$ play an important role in establishing the correspondence between the macroscopic and microscopic entropy. However, in this paper we will not be concerned with these entropy-carrying poles, instead we will restrict our attention mostly to the ones labelled by the elements of $Sp(2,\mathbb{Z})$ with $C=B=0$ and $A=(D^T)^{-1}$. These elements constitute the $SL(2,\mathbb{Z})$ subgroup of $Sp(2,\mathbb{Z})$ corresponding to the electric-magnetic or S-duality. Under the action of the element

$$\gamma=\begin{pmatrix} a & b\\ c & d\end{pmatrix}, \qquad ad-bc=1\ , \tag{2.9}$$

the charges P and Q transform into

$$\begin{pmatrix} P_\gamma\\ Q_\gamma\end{pmatrix}=\gamma\begin{pmatrix} P\\ Q\end{pmatrix}\ . \tag{2.10}$$

The period matrix should transform in such a way that the exponent in the counting formula remains invariant, that is $\Omega\to\Omega_\gamma$ with

$$\Omega_\gamma=\left(\gamma^T\right)^{-1}\Omega\gamma^{-1}. \tag{2.11}$$

Hence, the poles of the Siegel modular form $\Phi(\Omega)$ corresponding to these $SL(2,\mathbb{Z})$ elements are located at

$$\Omega_\gamma^{\sharp}=0\ . \tag{2.12}$$

Due to the presence of these poles, one has to be careful with choosing the contour $\mathcal{C}$: the counting formula will "jump" when the contour crosses one of these poles. Therefore, strictly speaking the formula (2.4) for $D(P,Q)$ is not just a function of the charges P and Q but also depends on the contour.

One of the problems with this contour dependence is that it obscures the invariance of the counting formula under the S-duality. As mentioned before, the exponential factor in the degeneracy formula (2.4) is invariant under the simultaneaous $SL(2,\mathbb{Z})$ transformation of the charges and Ω

$$e^{-i\pi\left(\begin{smallmatrix}P\\Q\end{smallmatrix}\right)^\dagger\Omega\left(\begin{smallmatrix}P\\Q\end{smallmatrix}\right)} = e^{-i\pi\left(\begin{smallmatrix}P_\gamma\\Q_\gamma\end{smallmatrix}\right)^\dagger\Omega_\gamma\left(\begin{smallmatrix}P_\gamma\\Q_\gamma\end{smallmatrix}\right)}\ , \tag{2.13}$$

while we also see from the $Sp(2,\mathbb{Z})$ transformation property (2.6) that the modular form is invariant under the transformation of its argument: $\Omega \to \Omega_\gamma$. Furthermore, using the fact $P^2, Q^2 = 0$ mod 2 and $ad+bc=1$ mod 2 one shows that

$$(-1)^{(P\cdot Q)} = (-1)^{(P_\gamma\cdot Q_\gamma)}. \tag{2.14}$$

Therefore the integrand of the degeneracy formula (2.4) is invariant under S-duality. This fact is not yet sufficient, however, to prove the invariance of the degeneracies. Namely, due to the presence of the poles, the expression for $D(P,Q)$ fails to be S-duality invariant, unless the contour $\mathcal{C}$ is also transformed to a new contour $\mathcal{C}_\gamma$. Namely, the equality

$$\oint_{\mathcal{C}} d\Omega\, \frac{e^{-i\pi\left(\begin{smallmatrix}P\\Q\end{smallmatrix}\right)^\dagger\Omega\left(\begin{smallmatrix}P\\Q\end{smallmatrix}\right)}}{\Phi(\Omega)}\,(-1)^{(P\cdot Q)} \;=\; \oint_{\mathcal{C}_\gamma} d\Omega_\gamma\, \frac{e^{-i\pi\left(\begin{smallmatrix}P_\gamma\\Q_\gamma\end{smallmatrix}\right)^\dagger\Omega_\gamma\left(\begin{smallmatrix}P_\gamma\\Q_\gamma\end{smallmatrix}\right)}}{\Phi(\Omega_\gamma)}\,(-1)^{(P_\gamma\cdot Q_\gamma)} \tag{2.15}$$

only holds when upon inserting (2.11) on the r.h.s., the new contour $\mathcal{C}_\gamma$ in the Ω_γ-plane is the same as $\mathcal{C}$ in the Ω-plane.

The contours $\mathcal{C}$ and $\mathcal{C}_\gamma$ are really different, and in general cannot be deformed into one another without picking up any residue. Therefore, one concludes that under S-duality the choice of contour has to change. A natural way to achieve this is to let the contour depend on the charges, and possibly also the moduli fields, since these quantities do transform under S-duality. Indeed, there is an important reason to suspect that the dyon counting formula is moduli-dependent, since it is known that certain multi-centered BPS solutions only exist in some range of background moduli and decay when a wall of marginal stability is crossed. The aim of this paper is to determine the charge and moduli dependence of the contour, so that it is consistent with S-duality and also takes into account the decay of dyonic bound states.

3 Contour Dependence and Pole Contributions

In this section we will examine the contour dependence of the dyon counting formula in details. For this discussion it will be convenient to parametrize the elements of Ω explicitly as

$$\Omega = \begin{pmatrix} \rho & \nu \\ \nu & \sigma \end{pmatrix} . \tag{3.1}$$

In terms of these quantities, the formula for the microscropic dyon degeneracies $D(P,Q)$ takes the form

$$-\oint_{\mathcal{C}} d\rho d\sigma d\nu \, \frac{e^{-i\pi(P^2\rho+Q^2\sigma+(P\cdot Q)(2\nu+1))}}{\Phi(\rho,\sigma,\nu)} , \tag{3.2}$$

where $\mathcal{C}$ is a contour in the Siegel domain defined by

$$\mathrm{Im}\rho > 0, \qquad \mathrm{Im}\sigma > 0, \qquad \mathrm{Im}\rho\,\mathrm{Im}\sigma > (\mathrm{Im}\nu)^2.$$

In the original proposal of [1], the degeneracies were expressed in terms of the expansion coefficients of $1/\Phi$ in powers of $e^{2\pi i\rho}$, $e^{2\pi i\sigma}$, and $e^{2\pi i\nu}$. As explained above, this prescription is somewhat ambiguous, since the expansion will depend on the location of the contour with respect to the poles.

So let us have a closer look at the possible choice of the contour $\mathcal{C}$ in (3.2). Due to the fact that we are dealing with a modular form, the contour will have to be inside a fundamental domain of the $Sp(2,\mathbb{Z})$ modular group. A natural choice of contour is to perform the integral over the real parts of ρ σ and ν, while keeping the imaginary parts fixed. Specifically, the integration range of the real variables is

$$0 \le \mathrm{Re}\rho, \mathrm{Re}\sigma, \mathrm{Re}\nu < 1 . \tag{3.3}$$

The integration contour is thus a three-torus. The location of the contour is determined by a choice of the imaginary parts. To make sure that $1/\Phi$ has a well-defined expansion up to high order, we will choose these imaginary parts so that Ω lies well inside the Siegel upper half plane, that is

$$\det(\mathrm{Im}\Omega) = \mathrm{Im}\rho\,\mathrm{Im}\sigma - (\mathrm{Im}\nu)^2 \gg 1 . \tag{3.4}$$

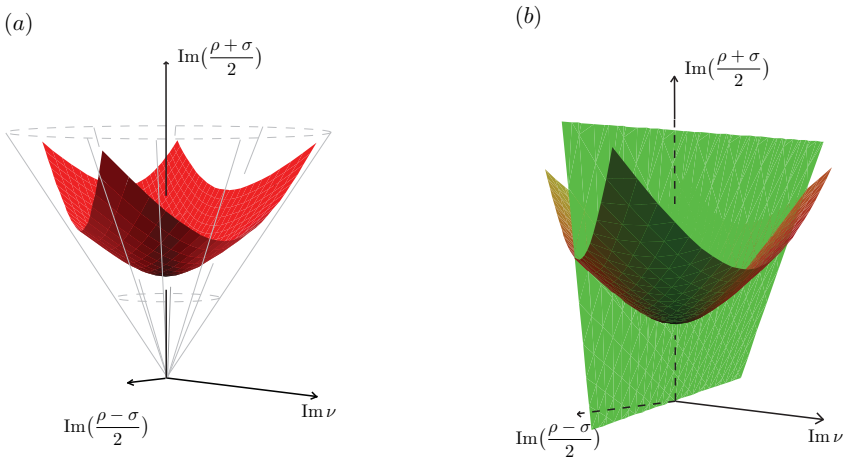

Figure 1: **(a)** The Siegel upper-half plane for the modular form Φ is the future light-cone in the Minkowski space $\mathbb{R}^{1,2}$, and we consider the space of all contours to be a sheet of hyperboloid inside this light-cone, with all the points on the hyperboloid having a large distance from the origin. **(b)** A pole corresponding to an element $\gamma \in SL(2,\mathbb{Z})$ is a plane in $\mathbb{R}^{1,2}$ which always intersects the hyperboloid along a hyperbola.

To visualize the location of the poles relative to the contours, it is convenient to regard the vector

$$(\mathrm{Im}\rho, \mathrm{Im}\sigma, \mathrm{Im}\nu) \in \mathbb{R}^{1,2}$$

as a vector in a three dimensional Minkowski space, with $\det(\mathrm{Im}\Omega)$ playing the role of the $SO(1,2)$ invariant inner product. The Siegel domain corresponds to the space inside the future light-cone, while the space of contours for a given large value of $\det(\mathrm{Im}\Omega)$ is identified with a sheet of a hyperboloid far out inside the future light-cone. This is shown in Figure [1]. As mentioned before, all the double poles of the generating function $1/\Phi$ are located at divisors given by the $Sp(2,\mathbb{Z})$ modular images of the divisor $\nu = 0$ in the (ρ, σ, ν) space. The location of this $\nu = 0$ divisor can be viewed as a hyperplane which transversely intersects the space of contours. The location of the other poles can be obtained by acting with the $Sp(2,\mathbb{Z})$ group. Note that the $Sp(2,\mathbb{Z})$ group action can be identified with that of the conformal group of

$\mathbb{R}^{1,2}$. This fact can be used to show that these general divisors take the form

$$\begin{aligned} k\rho + \ell\sigma + m\nu + r\,(\rho\sigma - \nu^2) + s &= 0 \quad \text{with} \\ k,\ell,m,r,s \in \mathbb{Z} \quad , \quad m^2 - 4k\ell + 4rs &= 1\ . \end{aligned} \tag{3.5}$$

The poles at divisors with $r = 1$ have exponentially dominant contribution to the degeneracy formula (3.2) compared to the rest in the case of large charges, as explained in the appendix of [1]. In [12] it was observed that the contour space (3.4) does not intersect any of the poles having $|r| \geq 1$. Indeed, a look at the real part of the above equation reveals that, since all the entries of $\mathrm{Re}\Omega$ run between 0 and 1, there is nothing to compensate the large contribution from $\det(\mathrm{Im}\Omega) \gg 1$ contained in the real part of $\rho\sigma - \nu^2$. Hence, these poles will always contribute to the degeneracy formula no matter which contour we choose, since they lie lower in the light-cone. Therefore, we never run into the danger of having a contour which crosses one of these poles. For our purpose of studying the contour dependence of the integral, it is therefore sufficient to concentrate on the poles with $r = 0$.

Since we are only interested in the poles inside the real domain of integration (3.3), we can restrict our attention to the poles with $r = s = 0$. It is easily seen that these are the images of the pole $\nu = 0$ under the $SL(2,\mathbb{Z})$ subgroup of $Sp(2,\mathbb{Z})$, and hence can be labelled by the group elements γ of $SL(2,\mathbb{Z})$[6]. Specifically, in terms of the integral matrix elements a, b, c, and d of γ we have

$$k = -bd, \qquad \ell = -ac \qquad m = ad + bc\ ,$$

where the length condition

$$m^2 - 4k\ell = (ad + bc)^2 - 4abcd = 1 \tag{3.6}$$

follows directly from $ad - bc = 1$. The plane inside $\mathbb{R}^{1,2}$ defined by the imaginary part of the equation (3.5) for this case can thus be written as

$$\mathrm{Im}(-bd\,\rho - ac\,\sigma + (ad + bc)\nu) = 0\ . \tag{3.7}$$

[6]One can show this by, for example, classifying both sets of numbers (a,b,c,d) and (k,ℓ,m) by their prime factorizations.

The length condition (3.6) implies that the normal vector to the plane is spacelike, and hence these planes always intersect the contour space hyperboloid (3.4) along a hyperbola. Therefore, each plane divides the contours into two sub-classes in a way analogous to the pole $\nu=0$ (see Figure [1]). Whether the corresponding poles contribute to the degeneracy formula for a given charge configuration will therefore depend on the contour we choose.

Let us now determine the condition under which these poles contribute, and, if they do, calculate their contribution. We first concentrate on the double pole at $\nu = 0$. Near the $\nu = 0$ divisor the generating function has the limit

$$\frac{1}{\Phi(\rho,\sigma,\nu)} = -\frac{1}{4\pi^2}\frac{1}{\nu^2}\frac{1}{\eta^{24}(\rho)}\frac{1}{\eta^{24}(\sigma)}\left(1+\mathcal{O}(\nu^2)\right) . \tag{3.8}$$

Notice that the last two factors in the limiting expression (3.8) are exactly the generating function for the 1/2-BPS degeneracies (2.1). By plugging the expression (3.8) into the degeneracy formula (3.2) and after performing the integration over the real part of ρ and σ, one gets

$$\frac{(-1)^{P\cdot Q}}{4\pi^2} d(P)d(Q) \oint_{\mathcal{C}_\nu} d\nu \, \frac{e^{-2\pi i(P\cdot Q)\nu}}{\nu^2} ,$$

where we have made use of (2.1). To evaluate the remaining integral over ν, we first consider a contour with $\mathrm{Im}\nu > 0$. For this case the contour is shown in the Figure [2]. When the charges under consideration satisfy $P \cdot Q < 0$, one can deform the contour to the upper infinity of the cylinder ($\mathrm{Im}\nu \to \infty$) where the integrand is zero without crossing any pole. One thus concludes that the integral yields zero. On the other hand, in the case $P \cdot Q > 0$, the contour can be moved to the lower infinity ($\mathrm{Im}\nu \to -\infty$) where the integrand is again zero, but now by doing so we pick up the contribution of the pole

$$-2\pi i \partial_\nu (e^{-2\pi i(P\cdot Q)\nu})|_{\nu=0} = -4\pi^2 \, (P\cdot Q) , \tag{3.9}$$

where the extra minus sign comes from the fact that we are enclosing the pole in a clockwise direction. For the contours with $\mathrm{Im}\nu < 0$, a similar argument shows that the pole only contributes when $(P \cdot Q) < 0$, but now with the opposite sign as above due to the reverse orientation in which the pole is enclosed. One therefore concludes that the contribution of this specific pole to the degeneracy formula (2.4) is

$$(-1)^{(P\cdot Q)+1} \, |P\cdot Q| \, d(P)\, d(Q) \qquad \text{when} \quad (P\cdot Q)\,\mathrm{Im}\nu > 0 \tag{3.10}$$

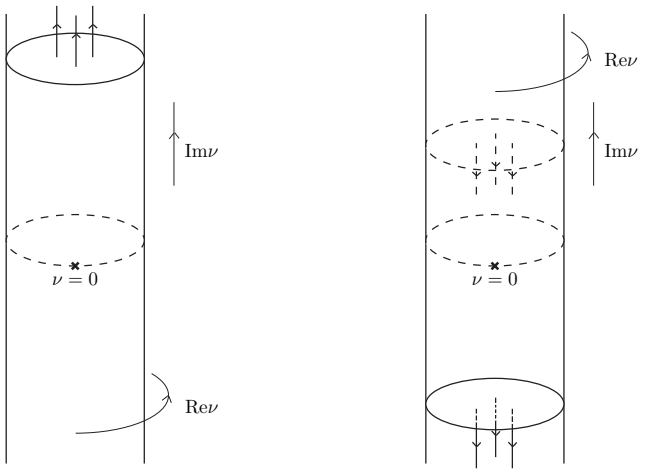

Figure 2: In this figure we show how the pole located at $\nu = 0$ contributes to the degeneracy formula for contours with $\mathrm{Im}\nu > 0$. **(a)** For charges with $P \cdot Q < 0$, one can deform the contour to the upper infinity of the cylinder where the integrand goes to zero without hitting the pole. **(b)** For charges with $P \cdot Q > 0$, one can deform the contour to the lower infinity of the cylinder, and by doing so pick up the residue of the pole.

and zero otherwise. The contributions of the other poles can be determined directly in a similar fashion. However, they are more easily obtained by making use the fact that they are the $SL(2,\mathbb{Z})$ images of the $\nu = 0$ pole. Together with the fact that the integrand is invariant under S-duality (2.15), it follows that the double pole of $1/\Phi$ located at

$$\nu_\gamma \equiv -bd\,\rho - ac\,\sigma + (ad + bc)\nu = 0 \tag{3.11}$$

gives the contribution

$$(-1)^{P_\gamma \cdot Q_\gamma + 1}\,|P_\gamma \cdot Q_\gamma|\,d(P_\gamma)\,d(Q_\gamma) \qquad \text{when} \quad (P_\gamma \cdot Q_\gamma)\,\mathrm{Im}\nu_\gamma > 0 \tag{3.12}$$

and zero otherwise. The equation (3.12) summarizes all the contour dependence in the degeneracy formula (3.2).

As we will see, the jumps in the counting formula when a contour crosses one of the poles are related to the decay of marginally bound 1/2-BPS particles. Specifically, we will argue that (3.10) precisely counts the number of states associated with the bound state of a purely electric 1/2-BPS object and a purely magnetic 1/2-BPS object, while (3.12) is associated with more general dyonic bound states that are obtained

by electric-magnetic duality. This interpretation will be discussed in more details in section 5, after we describe the supergravity solution corresponding to these states.

4 Dying Dyons and Walls of Marginal Stability

The central charge in the $\mathcal{N}=4$ supersymmetry algebra can be written as

$$\hat{Z} = \frac{1}{\sqrt{\tau_2}}(P_L - \tau Q_L)^m \Gamma_m \ ; \ m = 1, .., 6 \ , \tag{4.1}$$

where $\tau = \tau_1 + i\tau_2$ is the usual complexified axion-dilaton field and the left-moving charges are given by a six-dimensional projection of the 28 dimensional charge vectors,

$$P_L = \mu_A^m \, P^A, \qquad Q_L = \mu_A^m \, Q^A \ ; \ A = 1, 2, ..., 28 \ . \tag{4.2}$$

Here μ_A^m is a 6×28 matrix comprised of the 6×22 moduli fields parametrizing the coset space $\frac{O(6,22)}{O(6)\times O(22)}$. Here and from now on all the moduli fields are evaluated at spatial infinity.

The square of the BPS mass is equal to the largest eigenvalue of $\hat{Z}^\dagger \hat{Z}$. One can choose the basis such that all the gamma matrices are hermitian, and one then finds

$$\hat{Z}^\dagger \hat{Z} = \frac{1}{\tau_2} |P_L - \tau Q_L|^2 \, \mathbb{1} - 2i P_L^m Q_L^n \Gamma_{mn} \ . \tag{4.3}$$

From the fact that the operator $iP_L^m Q_L^n \Gamma_{mn}$ satisfies

$$(iP_L^m Q_L^n \Gamma_{mn})^2 = |P_L \wedge Q_L|^2 \equiv Q_L^2 \, P_L^2 - (Q_L \cdot P_L)^2 \ , \tag{4.4}$$

one concludes that $\hat{Z}^\dagger \hat{Z}$ has the following two eigenvalues

$$|Z_{P,Q}|^2 \ = \ \frac{1}{\tau_2} |P_L - \tau Q_L|^2 + 2|P_L \wedge Q_L| \tag{4.5}$$

$$\text{and} \qquad |Z'_{P,Q}|^2 \ = \ \frac{1}{\tau_2} |P_L - \tau Q_L|^2 - 2|P_L \wedge Q_L| \ . \tag{4.6}$$

The complex number $Z_{P,Q}$ with the largest norm plays in theories with $\mathcal{N}=4$ supersymmetry the same role as the single central charge in $\mathcal{N}=2$ theories. In particular, it determines the BPS mass

$$M_{P,Q} = |Z_{P,Q}|$$

and will therefore simply be referred to as the central charge. By choosing a specific spinor basis one can also fix the phase of $Z_{P,Q}$. We denote it by $\alpha_{P,Q}$, *i.e.*

$$Z_{P,Q} = e^{i\alpha_{P,Q}} |Z_{P,Q}| \ . \tag{4.7}$$

Note, however, that this phase is not unambiguously defined, since it depends on the choice of the spinor basis. As we will explain later, the criterion that determines whether two 1/2-BPS objects form a bound state can be formulated as a condition on the relative phase between the central charges of different objects. This relative phase is independent of the choice of spinor basis, even though the overall phase of the central charges is not.

A related comment is the following. Consider the $SL(2,\mathbb{Z})$ duality transformation of the charges (2.10) and the axion-dilaton moduli (4.16), this transformation has the effect of shifting the phase of the central charges by

$$Z_{P,Q} \to e^{-i\alpha_\gamma} Z_{P,Q}, \qquad \alpha_\gamma = \arg(c\tau + d) \ . \tag{4.8}$$

Again, the phase shift is independent of the charges, therefore all the relative phases will indeed be duality invariant.

We are now interested in knowing when a dyonic bound state might decay. First we concentrate on the specific decay channel of a dyonic, 1/4-BPS state with charges (P,Q) splitting into two 1/2-BPS particles with charges $(P,0)$ and $(0,Q)$. For this case, the condition for a wall of marginal stability is

$$M_{P,Q} = M_{P,0} + M_{0,Q} \ , \tag{4.9}$$

which can be rewritten as

$$|Z_{P,Q}| = |Z_{P,0}| + |Z_{0,Q}| \ . \tag{4.10}$$

Using the fact that the total central charge obeys

$$Z_{P,Q} = Z_{P,0} + Z_{0,Q} \ , \tag{4.11}$$

one finds that the condition of marginal stability can only be satisfied when the phases of the central charges are aligned. An explicit expression for this condition can be obtained either by determining these phases, or directly from (4.9) by using the explicit

formula for the BPS mass. Both approaches require a little bit of manipulation, and lead to the condition

$$\frac{\tau_1}{\tau_2} + \frac{P_L \cdot Q_L}{|P_L \wedge Q_L|} = 0 \ . \tag{4.12}$$

The next step will be to consider the other ways in which a dyon can split into two 1/2-BPS particles, and determine the corresponding walls of marginal stability. By definition a 1/2-BPS state must have degenerate eigenvalues of the operator $\hat{Z}^\dagger \hat{Z}$ and thus have parallel electric and magnetic charges

$$|Z_{P,Q}|^2 = |Z'_{P,Q}|^2 \Leftrightarrow P \parallel Q \ . \tag{4.13}$$

As discussed in [12], these 1/2-BPS decay channels can be labelled by $SL(2,\mathbb{Z})$ elements as[7]

$$\begin{pmatrix} P \\ Q \end{pmatrix} = \gamma^{-1} \begin{pmatrix} P_\gamma \\ 0 \end{pmatrix} + \gamma^{-1} \begin{pmatrix} 0 \\ Q_\gamma \end{pmatrix} \equiv \begin{pmatrix} P_1 \\ Q_1 \end{pmatrix} + \begin{pmatrix} P_2 \\ Q_2 \end{pmatrix} , \tag{4.14}$$

where the two terms to the right of the equivalence sign are defined by the corresponding terms left of this sign. This equation shows that these bound states are basically the $SL(2,\mathbb{Z})$ transforms of the bound state of a purely electric particle with charge P_γ and a magnetic particle with charge Q_γ. Using the fact that the central charge $Z_{P,Q}$ is $SL(2,\mathbb{Z})$ invariant up to a phase, one finds the condition of marginal stability to be

$$|Z_{P,Q}|_\tau = |Z_{P_\gamma,0} + Z_{0,Q_\gamma}|_{\tau_\gamma} = |Z_{P_\gamma,0}|_{\tau_\gamma} + |Z_{0,Q_\gamma}|_{\tau_\gamma} \ , \tag{4.15}$$

where in the last two expressions the central charge is evaluated with the $SL(2,\mathbb{Z})$ transformed value of the axion-dilaton fields

$$\tau_\gamma \equiv \frac{a\tau + b}{c\tau + d} \ . \tag{4.16}$$

After a straightforward calculation, the position of the corresponding wall of marginal stability turns out to be precisely given by the $SL(2,\mathbb{Z})$ image of the one for the bound state of the purely electric and purely magnetic 1/2-BPS states. Namely, the walls of marginal stability for all two-centered 1/2-BPS splits are

$$\frac{\tau_{\gamma,1}}{\tau_{\gamma,2}} + \frac{(P_L \cdot Q_L)_\gamma}{|P_L \wedge Q_L|_\gamma} = 0 \ . \tag{4.17}$$

[7]Strictly speaking, the bound states are labeled by elements of $PSL(2,\mathbb{Z})$, since states related by exchanging the two particle are physically equivalent.

As mentioned in [12], the projection of the above wall of stability from the full 134 dimensional moduli space to the upper τ_γ-plane is a straight line. But when regarded in the original τ-plane, it is a circle for generic group elements γ.

The meaning of the presence of a wall of marginal stability is that a BPS bound state of two particles exists on one side of the wall and disappears when crossing into the other side. After deriving the location of the walls for these bound states, we would like to know on which side these states are stable and on which side unstable. For this purpose we need more information about the corresponding supergravity solutions.

Stability Conditions from the Supergravity Solutions

Let us now consider the four-dimensional $\mathcal{N} = 4$ supergravity theory describing the low energy limit of the heterotic string compactified on a six-torus. The metric part of a stationary solution reads

$$\begin{aligned} ds^2 &= -e^{-2U}(dt + \vec{\omega} \cdot d\vec{x})^2 + e^{2U} d\vec{x}^2 && (4.18) \\ e^{2U} &= |\mathcal{P} \wedge \mathcal{Q}| \equiv \sqrt{\mathcal{P}^2 \mathcal{Q}^2 - (\mathcal{P} \cdot \mathcal{Q})^2} && (4.19) \\ \vec{\nabla} \times \vec{\omega} &= \mathcal{P} \cdot \vec{\nabla} \mathcal{Q} - \mathcal{Q} \cdot \vec{\nabla} \mathcal{P} \ , && (4.20) \end{aligned}$$

where the indices are contracted using the standard $SO(6,22)$-invariant 28×28 matrix η_{AB}, for example $\mathcal{P}^2 \equiv \mathcal{P}^A \mathcal{P}^B \eta_{AB}$.

The 56 harmonic functions appearing in the above solution are

$$\begin{aligned} \mathcal{P}^A(\vec{x}) &= C^A + \sum_i \frac{P_i^A}{|\vec{x} - \vec{x}_i|} \\ \mathcal{Q}_A(\vec{x}) &= D_A + \sum_i \frac{Q_{A,i}}{|\vec{x} - \vec{x}_i|} \quad , \end{aligned} \tag{4.21}$$

with the 56 constants given by the asymptotic value of 23 complex scalar fields (the axion-dilaton moduli τ and the 22 complex moduli projected from the aforementioned

6×22 moduli) as[8]

$$C^A = -\mathrm{Im}\left(e^{-i\alpha_{P,Q}}\frac{\partial Z_{P,Q}}{\partial Q_A}\right)$$
$$D_A = \mathrm{Im}\left(e^{-i\alpha_{P,Q}}\frac{\partial Z_{P,Q}}{\partial P^A}\right) \quad , \tag{4.22}$$

where the P^A's and the Q_A's denote the total charges coming from all the centers. From this expression one immediately sees that these coefficients satisfy $Q_A C^A = P^A D_A$, since the central charge is linear in all charges.

For the specific two-center bound state considered earlier, the corresponding supergravity solution has harmonic functions given by

$$\mathcal{P}^A = C^A + \frac{P^A}{|\vec{x} - \vec{x}_P|}$$
$$\mathcal{Q}_A = D_A + \frac{Q_A}{|\vec{x} - \vec{x}_Q|} \quad . \tag{4.23}$$

In this case the coordinate distance between the two centers $|\vec{x}_P - \vec{x}_Q|$ is fixed by the integrability condition [16], obtained by taking the divergence of the both sides of (4.20), and reads

$$\frac{P \cdot Q}{|\vec{x}_P - \vec{x}_Q|} = -C^A Q_A \, . \tag{4.24}$$

After some algebra this becomes

$$\frac{P \cdot Q}{|\vec{x}_P - \vec{x}_Q|} = -\frac{|P_L \wedge Q_L|}{M_{P,Q}} \left(\frac{\tau_1}{\tau_2} + \frac{P_L \cdot Q_L}{|P_L \wedge Q_L|}\right) \quad . \tag{4.25}$$

Since the distance between the two centers is always a positive number, one finds that, in order for the bound state to exist, the expression on the r.h.s. must have the same sign as $P \cdot Q$. Therefore the bound state only exists when

$$-\left(P \cdot Q\right) \left(\frac{\tau_1}{\tau_2} + \frac{P_L \cdot Q_L}{|P_L \wedge Q_L|}\right) > 0 \, , \tag{4.26}$$

[8]By evaluating the $\mathcal{N} = 4$ central charge operator $\hat{Z}$ (4.1) in the eigen basis of $\hat{Z}^\dagger \hat{Z}$, one can write the BPS equations in a way analogous to the $\mathcal{N} = 2$ case [16]. Only 22 complex moduli made out of the 6×22 real moduli fields play a role in the solution. It is indeed known that the $\mathcal{N} = 4$ moduli space locally decomposes as a product of 22 vector-, 44 hyper-, and 1 tensor-multiplet scalars in the $\mathcal{N} = 2$ language (see, for example, [17]).

and decays when one tunes the background moduli to hit the wall where the above expression vanishes. More precisely, one finds that the distance between the two centers goes to infinity, and the bound state no longer exists as a localizable state.

For the other bound states of 1/2-BPS particles obtained by acting with an element γ of the electric-magnetic duality group there exist similar solutions. But in this case the harmonic functions will have a seemingly more complicated form than the $P|Q$ split studied above. More explicitly, now the harmonic functions and the corresponding integrability condition takes the form

$$\begin{aligned} \mathcal{P}^A &= C^A + \frac{P_1^A}{|\vec{x} - \vec{x}_{P_\gamma}|} + \frac{P_2^A}{|\vec{x} - \vec{x}_{Q_\gamma}|} \\ \mathcal{Q}_A &= D_A + \frac{Q_{A,1}}{|\vec{x} - \vec{x}_{P_\gamma}|} + \frac{Q_{A,2}}{|\vec{x} - \vec{x}_{Q_\gamma}|} \quad , \end{aligned} \tag{4.27}$$

and

$$\left(\frac{Q_2}{|\vec{x}_{P_\gamma} - \vec{x}_{Q_\gamma}|} + D \right) \cdot P_1 - \left(\frac{P_2}{|\vec{x}_{P_\gamma} - \vec{x}_{Q_\gamma}|} + C \right) \cdot Q_1 = 0 \, , \tag{4.28}$$

where $P_{1,2}$, $Q_{1,2}$ are given in terms of the original charges and the group element γ as (4.14). Plugging in the charges, and after some manipulations using (4.8), the above integrability can be written, as expected, in a similar form as above:

$$\frac{(P_\gamma \cdot Q_\gamma)}{|\vec{x}_{P_\gamma} - \vec{x}_{Q_\gamma}|} = -\frac{|P_L \wedge Q_L|}{M_{P,Q}} \left(\frac{\tau_{\gamma,1}}{\tau_{\gamma,2}} + \frac{(P_L \cdot Q_L)_\gamma}{|P_L \wedge Q_L|_\gamma} \right) \, . \tag{4.29}$$

Thus, following the same reasoning, one finds exactly the same stability condition

$$-(P_\gamma \cdot Q_\gamma) \left(\frac{\tau_{\gamma,1}}{\tau_{\gamma,2}} + \frac{(P_L \cdot Q_L)_\gamma}{|P_L \wedge Q_L|_\gamma} \right) > 0 \, , \tag{4.30}$$

but now with both the charges and the axion-dilaton transformed with $\gamma \in SL(2, \mathbb{Z})$.

5 The Contour Prescriptions and Their Interpretation

Let us now return to the problem of identifying the contour that should be used in the counting formula, so that it counts the right number of states for a given value of the moduli. The key observation which will allow us to find the right prescription

is that the contour dependence due to the crossing of the pole labelled by γ should exactly match the physical decay process of the corresponding dyonic bound state. For example, at the wall of marginal stability of the bound state of an electric 1/2-BPS particle with charge P and a magnetic 1/2-BPS particle with charge Q, one expects the degeneracy $D(P,Q)$ to be adjusted by a certain amount corresponding to the degeneracy of this $(P,0)$, $(0,Q)$ bound state. This degeneracy can be found in the following way [12, 13, 14]. Firstly, each of the two centers has its respective degeneracy $d(P)$, $d(Q)$, which is given by the 1/2-BPS partition function of the theory as (2.1). Secondly, there is an extra interaction factor due to the fact that the spacetime is no longer static. The conserved angular momentum, after carefully quantizing the system [18], turns out to be

$$2J+1 = |P\cdot Q| \ . \tag{5.1}$$

One therefore concludes that the jump in the counting formula when one crosses the wall of marginal stability from the stable to the unstable side is given by

$$D(P,Q) \to D(P,Q) + (-1)^{(P\cdot Q)}\,|P\cdot Q|\,d(P)\,d(Q) \ . \tag{5.2}$$

This jump in the degeneracy is precisely the contribution (3.10) that we found from the pole at $\nu = 0$! Similar jumps occur when one crosses the walls of marginal stability for the other dyonic states labelled by $SL(2,\mathbb{Z})$ elements γ. These jumps are again precisely given by the contributions (3.12) of the poles at $\nu_\gamma = 0$. In terms of the contour space parametrized by $\mathrm{Im}\rho$, $\mathrm{Im}\sigma$ and $\mathrm{Im}\nu$, we have shown that whether this pole contributes or not depends on the sign of $(P_\gamma\cdot Q_\gamma)\,\mathrm{Im}\nu_\gamma$, while from the supergravity solution we have learned that whether this bound state exists or not depends on the sign of the l.h.s. of (4.30). It is therefore natural to make the identification

$$\mathrm{Im}\nu_\gamma = -\Lambda\left(\frac{\tau_{\gamma,1}}{\tau_{\gamma,2}} + \frac{(P_L\cdot Q_L)_\gamma}{|P_L\wedge Q_L|_\gamma}\right) \ , \tag{5.3}$$

where Λ is a yet undetermined positive parameter. This equality actually constitutes an infinite number of equations, namely one for each element $\gamma \in SL(2,\mathbb{Z})$. It is not immediately clear that all these equations can be imposed without running into contradictions.

One way to show their mutual consistency is to work out both sides of the equation, and observe that the left as well as the right can be written as a sum of products of the integers a, b, c and d as in (3.11). By identifying the various terms one arrives at a prescription that is independent of these integers. In other words, in this way one finds that the infinite set of equations (5.3) are equivalent to the following three conditions

$$\mathrm{Im}\nu = -\Lambda\left(\frac{\tau_1}{\tau_2} + \frac{P_L\cdot Q_L}{|P_L\wedge Q_L|}\right)\ , \tag{5.4}$$

$$\mathrm{Im}\rho = \Lambda\left(\frac{1}{\tau_2} + \frac{Q_L\cdot Q_L}{|P_L\wedge Q_L|}\right)\ , \tag{5.5}$$

and

$$\mathrm{Im}\sigma = \Lambda\left(\frac{|\tau|^2}{\tau_2} + \frac{P_L\cdot P_L}{|P_L\wedge Q_L|}\right)\ . \tag{5.6}$$

These equations determine the location of the contour $\mathcal{C}$ in terms of the charges and moduli. To see that these equations are consistent with S-duality invariance, we better use a more clever way to write them. It will turn out to be convenient to introduce the 2×2 matrices

$$\mathcal{M}_\tau = \frac{1}{\tau_2}\begin{pmatrix} 1 & -\tau_1 \\ -\tau_1 & |\tau|^2 \end{pmatrix} \tag{5.7}$$

and

$$\mathcal{M}_{P_L,Q_L} \equiv \frac{1}{|P_L\wedge Q_L|}\begin{pmatrix} Q_L\cdot Q_L & -P_L\cdot Q_L \\ -P_L\cdot Q_L & P_L\cdot P_L \end{pmatrix}\ . \tag{5.8}$$

Notice that the first matrix is given in terms of the asymptotic value of the axion-dilaton moduli, while the second depends on the charges and contains the asymptotic Narain moduli. These matrices transform in an identical fashion under the electric-magnetic S-duality group, namely

$$\mathcal{M}_\tau \to \left(\gamma^T\right)^{-1}\mathcal{M}_\tau\gamma^{-1} \qquad\qquad \mathcal{M}_{P_L,Q_L} \to \left(\gamma^T\right)^{-1}\mathcal{M}_{P_L,Q_L}\gamma^{-1}\ . \tag{5.9}$$

It is important to note that these transformation rules are the same as those of Ω. We can now summarize the results of the previous section in terms of these matrices as follows. The location of the wall of marginal stability (4.17) labelled by the $SL(2,\mathbb{Z})$ element γ is given by the condition

$$\left(\left(\gamma^T\right)^{-1}(\mathcal{M}_\tau + \mathcal{M}_{P_L,Q_L})\,\gamma^{-1}\right)^\sharp = 0\ . \tag{5.10}$$

Here, the superscript $\sharp$ again denotes the off-diagonal component of the 2×2 matrix inside the brackets. Similarly, the location of the corresponding pole $\nu_\gamma = 0$ is given in terms of Ω by

$$\left(\left(\gamma^T\right)^{-1} \Omega \gamma^{-1} \right)^\sharp = 0 \, . \tag{5.11}$$

In this way we are naturally led to the following moduli-dependent contour prescription. The contour is determined by specifying the value for the imaginary part of Ω in terms of the matrices $\mathcal{M}_\tau$ and $\mathcal{M}_{P_L,Q_L}$ containing the background moduli. The prescription reads

$$\mathrm{Im}\Omega = \Lambda \left(\mathcal{M}_\tau + \mathcal{M}_{P_L,Q_L} \right) \tag{5.12}$$

with $\Lambda \gg 1$. Here Λ is taken to be large to ensure that the series expansion of $1/\Phi$ converges rapidly. Moreover, as explained earlier, for large Λ the contour avoids all other poles except the ones given by $\nu_\gamma = 0$. Also note that the identification (5.12) is consistent with the Siegel condition, since

$$\det(\mathrm{Im}\Omega) = \Lambda^2 \left(\frac{M^2_{P,Q}}{|P_L \wedge Q_L|} \right) \Big|_\infty > 0 \tag{5.13}$$

and the trace of $\mathrm{Im}\Omega$ is also easily seen to have the required sign. Using the results (5.10) and (5.11), one easily verifies that this contour precisely crosses the right poles at the walls of marginal stability to account for the correct jumps in the dyon degeneracies. Furthermore, note that the contour prescription leads to a manifestly S-duality invariant counting formula.

The Attractor Contour for Large Charges

For large charges corresponding to a macroscopic black hole, it is natural to ask what happens to our prescription when one takes the moduli at infinity to be at the attractor value. Since the attractor values of the moduli are completely determined by the charges, this procedure leads to a degeneracy formula that is independent of the moduli. At the attractor point in moduli space the following equations hold for the Narain moduli

$$P_R|_{\text{attr.}} = 0, \qquad Q_R|_{\text{attr.}} = 0 \, , \tag{5.14}$$

and the axion and dilaton are given by

$$\tau_1|_{\text{attr.}} = \frac{P \cdot Q}{Q^2}, \qquad \tau_2|_{\text{attr.}} = \frac{|P \wedge Q|}{Q^2} \ . \tag{5.15}$$

From these equations the attractor values of the matrices $\mathcal{M}_\tau$ and $\mathcal{M}_{P_L,Q_L}$ are easily determined. One finds

$$\mathcal{M}_\tau|_{\text{attr.}} = \mathcal{M}_{P_L,Q_L}|_{\text{attr.}} = \mathcal{M}_{P,Q} \ , \tag{5.16}$$

where the 2×2 matrix $M_{P,Q}$ is defined by

$$\mathcal{M}_{P,Q} \equiv \frac{1}{|P \wedge Q|} \begin{pmatrix} Q \cdot Q & -P \cdot Q \\ -P \cdot Q & P \cdot P \end{pmatrix}\Big|_\infty \ . \tag{5.17}$$

Here the inner products between the charges are again defined using the moduli-independent $SO(6,22)$ invariant metric. In this way, we find that at the attractor point our moduli-dependent contour reduces to the following moduli-independent expression

$$\text{Im}\Omega = 2\Lambda \mathcal{M}_{P,Q} \ . \tag{5.18}$$

Again the $SL(2,\mathbb{Z})$ invariance is manifest, since both sides transform in the same way, and hence this prescription also leads to a S-duality invariant counting formula. But what are the states that are being counted by this formula? In fact, we will now argue that these are precisely the 1/4-BPS states that are not given by the bound states of two 1/2-BPS particles, and therefore cannot decay. Namely, when one fixes the moduli to be at the attractor values, the stability condition (4.26) reduces to

$$-2\frac{(P \cdot Q)^2_\gamma}{|P \wedge Q|} > 0 \ ,$$

which can clearly never be satisfied. In other words, none of the bound states of two 1/2-BPS particles can exist at the attractor moduli, which is a fact consistent with the general phenomenon that an attractor flow always flows from the stable to the unstable side. In this sense, our moduli-independent contour prescription leads to a counting formula which counts only the "immortal" dyonic states that exist everywhere in the moduli space. Notice further that this class of contours is not defined for charges with negative discriminant, since they lie outside of the Siegel domain. Furthermore, they

do not have an attractor point, and there is no single-centered supergravity solution carrying these charges.

Finally we would like to briefly comment on the role of the number Λ in our proposed contours (5.12), (5.18). It can be seen as playing the role of a regulator for the convergence of the generating function. To see this, notice that when we take the contour according to our prescription (5.18), the contribution

$$\left| D(P,Q)\, e^{i\pi \binom{P}{Q}^\dagger \Omega \binom{P}{Q}} \right| = |D(P,Q)| e^{-4\Lambda\pi|P\wedge Q|} \sim e^S e^{-4\Lambda\, S} \tag{5.19}$$

of certain large charges to the partition function is highly suppressed when $\Lambda \gg 1$, and we are therefore left with a rapidly converging generating function.

6 Conclusion and Discussion

In this paper we establish the precise relation between the contour dependence of the microscopic formula and the presence/absence of bound states of two 1/2-BPS configurations in different parts of moduli space in the macroscopic supergravity theory. Furthermore we propose a moduli-dependent prescription for the integration contour, such that all these two-centered bound states are correctly counted by the counting formula. Therefore we arrive at the surprising and somewhat unexpected conclusion that the counting formula actually counts the degeneracies in *all* of the moduli space, and that there is a well-defined way to extract these degeneracies from the counting formula by choosing the contour appropriately. In particular, the counting formula has a built-in S-duality invariance when the prescribed contour is used. Furthermore, for large black hole charges, we also propose a second, moduli-independent contour by going to the attractor value of the moduli, using which only the "immortal dyons" which exist everywhere in the moduli space are counted.

But there are certainly things we do not yet understand about this counting formula. First of all, what are the meaning of the o ther poles which seem always to contribute? Poles with $r > 1$ in (3.5) give a correction to the index of order $e^{S/r} = e^{\pi|P\wedge Q|/r}$ for large charges, which suggests that they might account for a split of charges into r pieces in some way. It would be nice to understand better the role of other splittings of charges

in the BPS spectrum. A second but not unrelated question is, what are the spacetime interpretation of the modular group $Sp(2,\mathbb{Z})$? Resorting to the product expression for the generating function [1]

$$\frac{1}{\Phi(\Omega)} = \frac{1}{e^{2\pi i(\rho+\sigma+\nu)}} \prod_{(k,\ell,m)>0} \left(\frac{1}{1-e^{2\pi i(k\rho+\ell\sigma+m\nu)}}\right)^{c(4k\ell-m^2)} \tag{6.1}$$

reveals that all the poles susceptible to contour dependence are caused by the lowest-lying oscillators with multiplicity $c(-1) = 2$ (recall that $c(n) = 0$ for $n < -1$), and vice versa. This suggests that there might be a way of rewriting the generating function analogous to the sum over modular images of the polar terms as in [20, 21, 22, 14]. We hope to put these puzzles together and return to these issues in the future.

Another question to be asked is, how would the inclusion of higher-order corrections to the low energy effective action affect our macroscopic analysis? In which way does, if it does, the counting formula encode the information about these corrections?

Finally, this inverse of the modular form $\frac{1}{\Phi(\Omega)}$ seems to our knowledge to be the first example of a moduli-independent partition function, in the sense that the index is always summarized by the same generating function, but different expansion points must be used for different background moduli. This fact might shed some light on the enigma of the split state counting [14], which arises due to the presence of marginal stability walls in a $\mathcal{N} = 2$ setup. It would be very interesting to investigate whether some of the similar structure is also present in (some classes of) $\mathcal{N} = 2$, D=4 theories.

As for the CHL models, a dyon counting formula has been proposed for appropriate $\mathbb{Z}_N$ orbifolds of the above theory for $N = 2, 3, 5, 7$. In these theories, the rank of the gauge group is reduced and the S-duality group is now the following subgroup of $SL(2,\mathbb{Z})$:

$$\Gamma_1(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL(2,\mathbb{Z}) \; ; \; c = 0 \bmod N \; , a, d = 1 \bmod N \right\} . \tag{6.2}$$

Moreover, the family of the contour-dependent poles of the proposed generating function $\frac{1}{\tilde{\Phi}_k(\tilde{\Omega})}$, which is now a modular form of a subgroup of $Sp(2,\mathbb{Z})$, and the ways in which a dyon can split into two 1/2-BPS particles, are both modified compared to the original theory. Nevertheless, we find that they can again both be labelled by the elements of the S-duality group $\Gamma_1(N)$, and these poles again give the same jump of

index as the decaying of these bound states. In particular, following the same arguments we make exactly the same proposal (5.12) for the integration contour for the dyon counting formula of this class of models.

Acknowledgments

We would like to thank Atish Dabholkar and especially Frederik Denef for useful discussions. M.C. would like to thank the Galileo Galilei Institute for Theoretical Physics for the hospitality and the INFN for partial support during the completion of this work.
